Abstract

We study optimal dynamic lockdowns against Covid-19 within a commuting network. Our framework integrates canonical spatial epidemiology and trade models, and is applied to cities with varying initial viral spread: Seoul, Daegu and NYC-Metro. Spatial lockdowns achieve substantially smaller income losses than uniform lockdowns, and are not easily approximated by simple centrality-based rules. In NYM and Daegu—with large initial shocks—the optimal lockdown restricts inflows to central districts before gradual relaxation, while in Seoul it imposes low temporal but large spatial variation. Actual commuting responses were too weak in central locations in Daegu and NYM, and too strong across Seoul.

1 Introduction

Commuting networks are the backbone of cities, allowing interactions that are vital for economic growth. On a typical day, Manhattan receives as many commuters from neighboring counties as it has residents—about 1.6 million people. Two months after the onset of Covid-19, NYC metro commute flows were 49% below pre-pandemic levels. Weighing the economic costs against the benefits of stopping Covid-19, was this reduction too large or not large enough? To fight a highly infectious disease without a vaccine, public authorities must decide how to curtail movements. How should lockdown policies be set across locations and time? These questions have particular significance given the different patterns of lockdown implemented across locations connected via commuting and trade.1

In this paper we establish an efficient benchmark against which to measure the losses from uncoordinated or spatially uniform lockdown efforts. We study optimal dynamic lockdowns to fight pandemics in a commuting network using a framework that integrates standard spatial epidemiology and trade models.2 In the model, a disease spreads through interactions of commuters at the workplace. Lockdown policies reduce the real income of workers who stay at home, and, indirectly, impact other locations as these workers consume fewer goods or services.3 Our planning problem determines the fraction of each origin-destination commuting flow allowed to operate at each point in time, under a probability that a vaccine becomes available, to minimize the discounted economic costs and the loss of lives. A planner could control the full commuting matrix through policies that close businesses, preclude commutes from specific areas, or disclose publicly the location of confirmed cases so residents take precautionary measures, as in the case of Seoul (see Argente et al., 2020).

We apply the model using real-time commuting data across districts in two South Korean cities, Seoul and Daegu, and cellphone mobility data across counties in the NYC Metro area (NYM). By studying different cities, we can compare optimal pandemic-fighting strategies across intensities of the initial virus shock and contrast them with the observed commuting responses. We analyze Korean cities because Korea has tested for Covid-19 at greater intensities than most countries, making the timeline of their case data more reliable.4 Seoul is the largest city in Korea but experienced a very small caseload per capita, while Daegu (Korea’s fourth largest city) experienced

---

1At the state level, lockdown mandates were announced fairly uniformly across bordering U.S. states, with a mean difference of 4 days and a standard deviation of 3.5 days, although there has been variation in county-level policies as well. For example, New York, New Jersey, and Connecticut imposed almost simultaneous lockdown, while Illinois did so more than two weeks before Missouri (Raifman et al., 2020).

2The spatial SIR model that we formulate is closely related to the multi-city epidemic model in Arino and Van den Driessche (2003), in which the disease is transmitted from infected residents of location $i$ to susceptible residents of location $j$ when they meet in $k$. The quantitative trade model is in the style of Anderson and Van Wincoop (2003) and Eaton and Kortum (2002).

3Caliendo et al. (2018) and Monte et al. (2018) study diffusion of local shocks across and within cities in related gravity models.

4Korea had performed 0.878 tests per thousand people at the time of its 1000th patient compared to 0.086 in the U.S. Stock (2020), Manski and Molinari (2020), Korolev (2020), and Atkeson (2020a) discuss challenges that arise from infrequent testing of Covid-19.
the largest shock within Korea. We study NYM because of its economic importance and rapid spread.

We compute the optimal lockdown given the Covid-19 spread when lockdown policies were announced. The model matches pre-pandemic commuting flows and wages across locations (Korean districts and NYM counties). We estimate the transmission rate using data on the spatial distribution of new cases and commuting flows over time. To estimate the spatial frictions that determine the diffusion of lockdown through goods markets, we use confidential geocoded credit card expenditure data from Seoul.

Our first results show that the optimal lockdowns are not easily approximated by simple centrality-based rules. Instead, they depend on the geography of commute flows, real income, and the initial viral spread. In NYM and Daegu—where the virus initially spread very quickly—locations with high virus-diffusion potential are subject to a strict initial lockdown, eliminating 40% to 80% of pre-pandemic inflows depending on the city and location, which is relaxed over 3 to 6 months. In NYM, many locations are locked down early, but only the top-3 central locations (Manhattan, Brooklyn, and Bronx) are still closed after 100 days and remain so in the expectation that a vaccine arrives. In contrast, in Seoul—where the initial spread of Covid-19 was much smaller—the planner initially locks down only a few locations of relatively high centrality. As the virus spreads, the lockdown intensifies and retains considerable spatial variation.

Our second result shows large benefits from spatial targeting. Specifically, we find substantially lower real-income losses from allowing for spatial targeting compared to an optimal uniform lockdown (i.e., no spatial variation). Given the actual case count by April 30, spatial targeting would have led to 15%, 28%, and 50% lower economic costs in Daegu, Seoul, and NYM, respectively, than the optimal uniform lockdown.

Finally, we ask how the observed commuting reductions, resulting from a combination of government action and commuters’ self-imposed precaution, compare with the optimal benchmark. On average across locations, commuting declines reached troughs of 79.3%, 37.6%, and 81.5% below pre-pandemic levels in Daegu, Seoul, and NYM before modestly reverting upward. In NYM and Daegu, these city-level declines are broadly consistent with the optimal benchmark. However, the most central (peripheral) locations exhibited a weaker (stronger) reduction in commuting than what would have been optimal. In Seoul, actual commuting reductions were too strong compared to the optimal across the city. As a result, across all three cities, the real income losses could have been much smaller through optimal spatial targeting, given the actual case count.

Adda (2016) demonstrates the relevance of transportation networks for disease transmission by exploiting exogenous variation in public-transport strikes, and Viboud et al. (2006) show that work-
related flows correlate with the regional spread of influenza in the United States. Several empirical studies document that travel across and within cities contributed to the spread of Covid-19.\textsuperscript{5}

Early spatial SIR models were used to study influenza and measles (Rvachev and Longini Jr, 1985; Bolker and Grenfell, 1995). Several studies simulate specific policies but empirical applications of optimal lockdown in realistic environments are uncommon.\textsuperscript{6} For Covid-19, Chinazzi et al. (2020) simulate travel restrictions, Birge et al. (2020) study location-specific but time-invariant lockdown, Giannone et al. (2020) simulate reopening patterns, and Argente et al. (2020) consider case information disclosure.

Compared to this literature, our contribution is three-fold. First, we implement optimal lockdown over both time and space in a commuting network. Second, to evaluate the diffusion of economic costs through changes in spending we integrate a general-equilibrium trade framework. Third, we use real-time commuting data to estimate and compare the actual commuting responses over space with optimal lockdowns. Our analysis demonstrates large advantages of optimal spatial targeting.

2 Model

We use a standard spatial epidemiology model similar to Arino and Van den Driessche (2003). The general equilibrium corresponds to a standard quantitative gravity trade model as in Anderson and Van Wincoop (2003) and Eaton and Kortum (2002).

2.1 Spatial Diffusion

The economy consists of $N$ locations in continuous time. Before the pandemic, in each location $i$ there are $N_0(i)$ residents, of which a fraction $\lambda(i, j)$ commutes to $j$. We let $\Lambda$ be the matrix of bilateral commuting flows such that $[\Lambda]_{ij} = \lambda(i, j)$.\textsuperscript{7}

At each time $t$, the surviving residents of location $j$ are either susceptible, exposed, infected, or recovered in quantities $S(j, t)$, $E(j, t)$, $I(j, t)$, and $R(j, t)$, respectively. Susceptible agents become exposed after interacting with infected agents; exposed agents are latent carriers who do not infect others and become infected at rate $\gamma I$. Infected agents die at rate $\gamma_D$ or recover (and become immune) at rate $\gamma_R$. The spatial distributions are collected in the (column) vectors $S(t)$, $E(t)$, $I(t)$, and $R(t)$.

\textsuperscript{5}Tian et al. (2020) argue that the Wuhan lockdown and suspending intra-city public transport delayed the spread of Covid-19 across China, and Fang et al. (2020) use real-time movement data to show that the lockdown reduced infection rates. Kissler et al. (2020) show commuting correlates with cases across boroughs in New York. Hsiang et al. (2020) and Flaxman et al. (2020) present evidence that different interventions, including lockdown, reduced the spread. These papers do not implement a structural analysis or optimal lockdown.

\textsuperscript{6}See Bussell et al. (2019) for a recent literature review. E.g., Germann et al. (2006), Eubank et al. (2004) and Drakopolous and Zheng (2017) study targeted policies against epidemics in spatial or network SIR models. Theoretical properties of optimal control in spatial SIR models were studied by Rowthorn et al. (2009).

\textsuperscript{7}These initial distributions could be the equilibrium of a spatial model as in Redding and Rossi-Hansberg (2017). Given the time frame of the analysis we assume no job reallocation, so the distribution of jobs changes only due to lockdown.
The government can control the fraction \( \chi(i,j,t) \) of commuting flows from \( i \) to \( j \) by imposing lockdown measures, providing incentives, or sending signals through communication channels. Every agent is subject to the policy regardless of infection status. Among those not physically commuting, a fraction \( \delta_u, u = S, E, I, R \), telecommutes. Among the infected, only the asymptomatic fraction \( \zeta \) works. The lockdown policies are collected in the \( N \times N \) matrix \( \chi(t) \).

The geographic spread of the disease depends on how infected and susceptible people interact in space. The infections could happen anywhere at commuting locations, such as in train stations, workplaces, or restaurants.\(^8\) Let \( \tilde{S}(i,t) \equiv \sum_j \chi(j, i, t) \lambda(j, i) S(j,t) \) be the number of susceptible agents (from any origin) exposed in \( i \), and \( \tilde{I}(i,t) \equiv \zeta \sum_j \chi(j, i, t) \lambda(j, i) I(j,t) \) be the number of infected asymptomatic agents (from any origin) spreading the disease in \( i \). In matrix form, \( \tilde{S}(t) \equiv \mathbf{H}_S(t) \mathbf{S}(t) \) and \( \tilde{I}(t) \equiv \mathbf{H}_I(t) \mathbf{I}(t) \), where \( \mathbf{H}_S(t) \) and \( \mathbf{H}_I(t) \) are spatial incidence matrices that depend on pre-pandemic commuting flows and current lockdown policies:

\[
\mathbf{H}_u(\chi(t)) = \zeta_u (\mathbf{A} \cdot \chi(t))'
\]

for \( u = S, I \), where \( \zeta_I = \zeta \) is the fraction of infected asymptomatic commuters, \( \zeta_S = 1 \), and \( \cdot \) is the element-wise product. The \((ij)\) element of \( \mathbf{H}_S(t) \) is the exposure of the \( S(j, t) \) susceptible residents of location \( j \) to the \( \tilde{I}(i, t) \) infected agents commuting to \( i \). Similarly, the \((ij)\) element of \( \mathbf{H}_I(t) \) is the exposure of the \( I(j, t) \) infected residents of location \( j \) to the \( \tilde{S}(j, t) \) susceptible agents commuting to \( i \).

The flow of new infections taking place in \( i \) is

\[
M_i \left( \tilde{I}(i,t), \tilde{S}(i,t) \right),
\]

where \( M_i(\cdot) \) represents the matching process between infected and susceptible individuals in \( i \). The infections taking place in \( i \) are carried back by susceptible and infected agents to their residence. Of the infections taking place in \( i \), a fraction \( H_S(i, j, t) S(j, t) / \tilde{S}(i, t) \) corresponds to residents of \( j \). Therefore, the flow of the new infections among location \( j \)’s residents is:

\[
\dot{S}(j,t) = -\sum_i H_S(i, j, t) S(j, t) / \tilde{S}(i, t) M_i \left( \tilde{I}(i,t), \tilde{S}(i,t) \right).
\]

### 2.2 Real Income

The economic costs of lockdown enter through the distribution of real income,

\[
U(i,t) = \frac{Y(i,t)}{P(i,t)}.
\]

\(^8\)We could incorporate infections during trips by modeling the links in the transport network underlying the commuting matrix.
where $P(i,t)$ is the cost of living and $Y(i,t)$ is the nominal income of location-$i$ residents:

$$Y(i,t) = \sum_{u=S,E,I,R} \sum_{j} N_u(i,j,t) w(j,t), \quad (5)$$

Here, $w(j,t)$ is the wage per efficiency unit in $j$ at time $t$ and $N_u(i,j,t)$ is the flow of efficiency units of type-$u$ commuters from $i$ to $j$:

$$N_u(i,j,t) = \zeta_u [\chi(i,j,t) + (1 - \chi(i,j,t)) \delta_u] \lambda(i,j) u(i,t), \quad (6)$$

for $u = S, E, I, R$, where $\zeta_I = \zeta$ is the fraction of asymptomatic infected and $\zeta_u = 1$ for $u \neq I$. The efficiency units flowing from $i$ to $j$ include those physically commuting, $\chi(i,j,t)$, and those not commuting scaled by the fraction of telecommuters, $(1 - \chi(i,j,t)) \delta_u$.

The jobs at $j$ produce goods or services with productivity $z(j)$. Consumers have a constant elasticity of substitution $\sigma$ across goods from different locations. Residents of $j$ face trade costs $\tau(i,j) > 1$ when buying from $i$, which may include going to the store. In equilibrium, markets clear at all $t$:

$$w(i,t) \sum_{u=S,E,I,R} \sum_{j} N_u(j,i,t) = \sum_{j} s(i,j,t) Y(j,t) \text{ for all } i; \quad (7)$$

i.e., the total income of workers employed in $i$ equals the aggregate expenditures in goods from $i$, where $s(i,j,t) \equiv \left(\frac{\tau(i,j) w(i,t)}{P(j,t) z(i,t)}\right)^{1-\sigma}$ is the expenditure share of goods from $i$ in location $j$, and

$$P(j,t) = \left(\sum_{i} p(i,j,t)^{1-\sigma}\right)^{\frac{1}{1-\sigma}} \quad (8)$$

is the price index in $j$.

In equilibrium, $\{w(j,t), P(j,t)\}$ are such that (7) and (8) hold. The lockdown $\chi(i,j,t)$ affects the income of location-$i$ residents and the supply of goods and services at $j$. Lower income of location $i$ diminishes purchases from locations with lower trade costs to $i$, and the lower supply of goods at $j$ increases purchases from other locations. Empirically, these reallocations depend on the expenditure shares $s(i,j,t)$.

### 2.3 Planning Problem

A social planner chooses the lockdown matrix to maximize the present discounted value of real income net of loss of lives. The aggregate real income of location $j$ depends on the spatial distributions of lockdown and residents by infection status:

$$U(j,t) \equiv U(j; S(t), E(t), I(t), R(t), \chi(t)). \quad (9)$$

A vaccine and a cure become freely available with probability $\nu$ in every time period. If the cure occurs at time $t$, location $j$ generates the real income $\bar{U}(j,t) \equiv U(j; 0, 0, 0, S(t) + E(t) + I(t) + R(t), 1_{J \times J})$
forever. The planning problem is:

\[ W = \max_{\chi(t)} \int_0^\infty e^{-(r+\nu)t} \sum_j \left[ U(j,t) + \frac{\nu}{r} U(j,t) - \omega \gamma_D I(j,t) \right] dt \]  

(10)

subject to

\[
\begin{align*}
\dot{S}(t) &= -S(t) \cdot \left[ H_S(\chi(t))' \left( M \left( \frac{\dot{S}(t)}{\dot{S}(t)} , I(t) \right) \cdot /\dot{S}(t) \right) \right], \\
\dot{E}(t) &= -\dot{S}(t) - \gamma_I I(t), \\
\dot{I}(t) &= \gamma_I E(t) - (\gamma_R + \gamma_D) I(t), \\
\dot{R}(t) &= \gamma_R I(t)
\end{align*}
\]  

(11) \quad (12) \quad (13) \quad (14)

where \( M(\cdot) \) is a vector with the new matches, and where \( \dot{S}(t) = H_S(\chi(t)) S(t) \) and \( \dot{I}(t) = H_I(\chi(t)) I(t) \) are the susceptible and infected agents. The matrix \( \chi(t) \) controlled by the planner impacts aggregate real income and the spatial incidence matrix through (9) and (1).

3 Data and Parametrization

The parametrization uses case data and real-time commuting flows to estimate the virus transmission rate. The optimization is implemented starting at the lockdown announcement date using pre-pandemic data on commuting flows, wages, population, and spending. Our units of analysis are the 25 districts in Seoul and 8 districts in Daegu. We define NYM to be 20 counties: 5 NYC boroughs, 5 counties in NY (Putnam, Rockland, Westchester, Nassau, Suffolk), 8 counties in New Jersey (Bergen, Essex, Hudson, Middlesex, Morris, Passaic, Somerset, Union), and 2 counties in Connecticut (Fairfield, New Haven).

3.1 Data

Covid-19 Data

The Seoul Metropolitan government released patient-level case data. We filed an Official Information Disclosure Act request to obtain patient-level data from the Daegu Metropolitan government. We build a daily panel dataset with total confirmed cases in the Seoul and Daegu districts. County-level NYM cases come from Johns Hopkins University and the NY State Department of Health.\(^{11}\)

\(^{9}\)The planner’s utility from location \( j \) is:

\[ W_0(j,t) = (U(j,t) - \omega \gamma_D I(j,t)) dt + \nu dt e^{-r dt} \frac{U(j,t)}{r} + e^{-r dt} (1 - \nu dt) W_0(j,t + dt). \]

Solving for the present discounted value and adding up across locations yields (10).

\(^{10}\)The notation \( \cdot / \) stands for element-wise ratio.

\(^{11}\)The Korean data allow us to exclude cases arriving from overseas travels that were stopped at the border and quarantined.
There are limitations to using data on Covid-19 infections due to bias of the tested population and sensitivity of the tests. These limitations are more severe at the onset of the pandemic when testing intensity was low. Our estimation of the virus transmission rate uses data from the later periods when reporting and testing improved. These limitations are further mitigated in Korea where testing intensity has been high since the beginning.

**Daily Commuter Data**

For Seoul, we use district-to-district commute flows on the public transit system (subway and bus) through confidential individual trip-level data housed at the Seoul Big Data Campus. Passengers enter and exit public transit using a card with a unique identifier, from which we obtain the time, origin, and destination of each commute. We retain weekdays from 4am to 12pm (and 12pm to 8pm on weekends, since commutes start later) to capture the first commute leg. We aggregate over individual trips to bilateral commute flows across districts from January 2018 to April 2020. Pre-pandemic commute flows are the 2019 averages.

For Daegu, we measure daily commuting using subway turnstile data from January 2018 to April 2020, made available by Daegu Metro Transit Corporation. We retain entries and exits using the same commute window as in Seoul. Stations’ total entries (exits) plausibly capture the density of residents (jobs) if commuters enter (exit) the subway station closest to their residence (workplace). We aggregate the station-level data to the district level. Pre-pandemic commute flows come from the 2015 Korean Population Census which records where people live and work.

For NYM, we measure county-to-county daily movements using cellphone data from SafeGraph (real-time turnstile data within NYC is not available for suburban commuter rails). The data cover the period from January 1, 2020 to April 30, and are constructed from anonymized smartphone movement data collected daily at the Census block level. We aggregate these data to the NYM counties. Pre-pandemic commute flows for NYM are the averages from January 1-20.

Appendix Table A.1 summarizes the commuter data and dates of key events described in the next subsection.

**Wages and Population**

Population and wage data for the Korean districts come from the 2019 resident registration database and the 2019 Statistical Yearbook of National Tax, respectively. NYM county wages are constructed from the 2017 LEHD Origin-Destination Employment Statistics, which reports the number of workers by wage bin and Census block. Bins are defined as lower than $1250, between $1250 and $3333, and above $3333 per month.

---

12 SafeGraph provides the fraction of people who stay within their residence, allowing us to separate the within-county flows into those who stay at home and those who commute to work within their county.
13 Bins are defined as lower than $1250, between $1250 and $3333, and above $3333 per month.
Credit Card Spending

We access confidential data on the universe of transactions using credit and debit cards issued by one of the top 3 banks in Korea, from the Seoul Big Data Campus. The data contain transactions at brick-and-mortar shops within Seoul. We observe the addresses of cardholders and business, and the dollar values. We construct an average daily district-to-district spending matrix for 2019 among the 25 districts of Seoul, restricting the data to spending by Seoul residents. We use this data to estimate a pre-pandemic trade-to-distance elasticity and a same-district spending share to estimate the key parameters of the within-city trade block of the model.

3.2 Commuting Responses

Figure 1 plots time fixed effects for commuting flows relative to pre-pandemic averages since January 2020 in each city.\textsuperscript{14} In each figure the first vertical line denotes the first confirmed case in the country, the middle line denotes the first case in the city, and the last line is the date of the lockdown announcement. We overlay the daily counts of new Covid-19 scaled by city population.\textsuperscript{15}

Before the first confirmed case within Korea on January 26, we observe no trends in commutes. That day, ridership fell by roughly 10% relative to pre-pandemic levels.\textsuperscript{16} After the first confirmed case within Daegu on February 17, the virus spread quickly and commute responses declined steeply. In Seoul, there was no further change after the first confirmed case within the city on January 30. The right axes show that the spread was much larger in Daegu than in Seoul, which may explain the different commute responses.

After the virus spread throughout Korea during February, a national task force laid out guidelines that included social distancing, working from home, canceling non-essential gatherings, and postponing the start date for schools and universities. Following the announcement of these guidelines on February 24, public transit ridership continued to fall in both cities for roughly two weeks before trending back upwards. Overall, ridership fell 60.2% and 34.9% in Daegu and Seoul, respectively. The standard errors suggest similar responses across districts.

In contrast, in NYM we do not observe declines in commuting before the first confirmed within-city case on March 3. New York State issued a lockdown order on March 22 that closed non-essential businesses.\textsuperscript{17} At the time of the lockdown announcement, commuting patterns were already trending downward and continued to fall until mid-April, at which point commuting was 70.1% below

\textsuperscript{14}For Seoul and NYM, where we observe bilateral commute flows, we estimate \( \frac{N_{ij,t}}{\bar{N}_{ij,\tau(t)}} = \pi_t + \epsilon_{ij,t} \). The dependent variable is bilateral commute flows on date \( t \) relative to average pre-pandemic flows and the \( \tau(t) \) is a day-of-week and month dummy to control for seasonality and daily variation. For Daegu, since the raw data are from turnstiles, this figure reports \( \frac{E_{it}}{\bar{E}_{i,\tau(t)}} = \pi_t + \epsilon_{it} \), where the dependent variable is daily entries. The figure reports the \( \pi_t \) coefficients for each city. Standard errors are two-way clustered by origin and destination in Seoul and NYM, and by origin in Daegu using the wild bootstrap to account for the small number of clusters (Cameron et al., 2008).

\textsuperscript{15}Following Fang et al. (2020) we find a positive correlation between lags of commuting and new daily infections after controlling for location and date fixed effects. See Appendix B.

\textsuperscript{16}Commuting falls one day before the first confirmed case due to a holiday.

\textsuperscript{17}New Jersey and Connecticut locked down a few days earlier but we assign the NY’s lockdown date since Manhattan is the central node.
the pre-pandemic flows.

### 3.3 Parametrization of the Model

To bring the model to the data the frequency is set to daily. Appendix Table A.2 summarizes the parameters and Appendix A describes the numerical resolution method.

**Disease Dynamics**

Following Ferguson et al. (2020) we set $\gamma_I$ consistent with an incubation period of 5.1 days and as robustness also consider 4.2 days (Sanche et al., 2020). Following Wang et al. (2020) we set $\gamma_R$ consistent with a recovery time of 18 days and also show results assuming 10 days. Ferguson et al. (2020) obtain an infection fatality ratio of 0.9%, which we use as benchmark, and we also show results using a lower bound of 0.3% across studies (Hall et al., 2020). Alamian et al. (2019) estimate that 36% of cases infections are asymptomatic.\(^{18}\) We use this number as benchmark and half that rate as robustness. For $\delta_u$, Dingel and Neiman (2020) report that 46% of jobs in the U.S. could be done from home. A survey by Job Korea says that 60% of workers can telecommute.\(^{19}\) The probability of finding a vaccine is such that the expected time until arrival is 18 months.\(^{20}\) $\rho$ matches an annual interest rate of 4%.

As benchmark we impose a value of life $\omega$ of 10 million USD above the expected present discounted value of wages, and also implement the analysis for values between 1/100 and 100 times the benchmark to trace a Pareto frontier.

**Matching Function and Transmission rate**

As is standard in the SIR model, we impose a multiplicative matching function. The total number of new infections taking place in location $j$ is

$$M_j(\tilde{I}_j, \tilde{S}_j) = \beta_j \tilde{I}_j \tilde{S}_j.$$  \(^{(15)}\)

$\beta_j$ is a location-specific transmission rate capturing that some locations are more prone to contagion. We assume that, given the number of individuals interacting in a location, contagion is more prevalent in denser districts:\(^{21}\)

$$\beta_j = \frac{\beta}{\text{area}_j}. \quad (16)$$

We set $\beta$ to match the model-based infection dynamics to Covid-19 case data. Using (3) and

\(^{18}\)This number equals the ratio between asymptomatic infections (12%) and infections (33%) in their sample.  
\(^{21}\)This adjustment ensures that the aggregate infections are invariant to spatial aggregation. In an SIR model with $S$ susceptible and $I$ infected individuals equally divided among $N$ locations, assuming away spatial interactions the aggregate number of infections is $SI/N$, so that slicing a territory reduces infections. Normalizing the transmission rate by area yields instead $SI$, which is invariant to the number of locations.
The change in the number of susceptible agents is:

$$\Delta S(i,t) = -\beta \zeta \left[ \sum_j \frac{1}{area_j} \chi(i,j,t) \lambda(i,j) \sum_{j'} \chi(i',j,t) \lambda(i',j) I(i',t) \right] S(i,t) + \varepsilon(i,t), \quad (17)$$

where $\lambda(i,j)$ is the pre-pandemic fraction of residents from $i$ commuting to $j$ at time $t$, $\chi(i,j,t)$ is the commuting from $i$ to $j$ at time $t$ relative to pre-pandemic flows, and $\varepsilon(i,t)$ accounts for measurement error and other forces driving infections. We observe $\lambda(i,j,t) \chi(i,j,t)$ for Seoul and NYM, and for Daegu we apply the changes in entries and exits to the pre-pandemic flows to construct its bilateral flows. $S(i,t)$ and $I(i,t)$ are recovered from data on new infections, the calibrated transition rates, and the laws of motion (11) to (13). Given the asymptotic rate $\zeta$, we set $\beta$ to minimize the sum of square errors $\sum_i \sum_t \varepsilon(i,t)^2$.

To mitigate concerns that the new cases data is imprecise and driven by testing, we start the estimation 10 days after the peak in new cases in each city. This approach is consistent with the assumptions that the data on new cases became more precise in the latest periods. The results are very similar if we start the estimation at the peak.

Appendix Figure A.1 shows that the model replicates well the average number of new cases after the peak in the data, and implies a fair amount of dispersion in the dynamics across locations. For the first week after patient zero, the estimation implies a city-level reproduction number (the number of new infections per infected individual) of 1.38 in Seoul, 1.32 in Daegu, and 2.27 in NYM. These numbers are in line with existing estimates; e.g., Shim et al. (2020) estimate 1.5 in Korea and Fernández-Villaverde and Jones (2020) estimate 2.5 in New York.\footnote{22}

**Trade Model Parameters**

We now parametrize the trade costs $\tau(i,j)$ and the productivities $z(i)$. We follow the approach in gravity models of specifying trade costs as a log-linear function of distance,

$$\tau(i,j) = \kappa_0 distance(i,j)^{\kappa_1} \quad (18)$$

for $i \neq j$ and $\tau(i,j) \equiv 1$. Adding an error term we obtain the gravity equation:

$$\ln X(i,j) = \psi(j) + \eta(i) - (\sigma - 1) \kappa_1 \ln (distance(i,j)) + \varepsilon(i,j) \quad (19)$$

where $X(i,j)$ are district $j$’s expenditures in goods and services produced by district $i$, and $\psi(j)$ and $\eta(i)$ are destination and origin fixed effects. Using the credit-card spending data from Seoul we estimate a coefficient on log distance $(\sigma - 1) \kappa_1 = 1.48 \pm 0.034$.\footnote{23 As in Ramondo et al. (2016), the reproduction number is the largest eigenvalue of the matrix diag($S(t)$)$H_S$diag($\beta$)$H_I$/$\gamma_D + \gamma_R$ (Diekmann et al., 1990). Appendix Table A.2 reports the estimates of $\beta$. The scale of $\beta$ is not comparable to existing estimates in single-location models because of our spatial structure.}

Robust standard error in parenthesis. Monte et al. (2018) estimate 1.29 using the bilateral trade flows between 123 Commodity Flow Survey regions.
we set $\sigma = 5$ to recover $\kappa_1$. Then, for each city, we recover the distribution $z(i)$ and set the scale parameter $\kappa_0$ to match the pre-pandemic data on wages $w(j)$ and the fraction of same-district expenditures in total expenditures, respectively. The latter is 55% in the Seoul credit-card data, and assumed to be the same across cities.

4 Optimal Spatial Lockdowns

4.1 Centrality and Optimal Lockdown

We implement the model in each city. As initial condition, we use the spatial distribution of cases at the lockdown date. The left panel of Figure 2 shows maps with eigenvector centrality by location. This measure captures the potential of each location to diffuse Covid-19 if no lockdown is implemented.\footnote{It is defined as the eigenvector of the largest eigenvalue of the matrix governing viral spread at time 0, \( \text{diag}(S(0))H_{s}\text{diag}(\beta)H_r \).} The right panel shows the fraction of commuting inflows that is optimally shut down relative to pre-pandemic flows.

We find similar qualitative patterns in NYM and Daegu. The most central locations first experience a strong lockdown, of between 50%-80% in New York and 40%-60% in Daegu. In both cities the lockdown of central locations is relaxed over 3 to 6 months, eventually affecting 5%-40% of inflows in the most central NYM locations and 10%-30% in Daegu. In NYM, other locations also exhibit an early lockdown but only the top 3 central counties are closed after 100 days. In Daegu, a few peripheral locations exhibit strict lockdown for a long time.

These patterns contrast with Seoul, where despite the limited spread, the planner imposes a lockdown for a long period to restrain the growth of the disease. The planner first locks down a few locations of high centrality for Covid diffusion, but maintains economic activity. After the disease has spread, the lockdown intensifies across most locations.

The results demonstrate that no simple statistic guides the optimal lockdown. Instead, the optimal strategies over time and space depend on the full geography of commute patterns and real income, and on the initial viral spread. When the spread is sufficiently large, the planner first places more weight on shutting down locations that are perceived as transmission hubs, even if they are the main sources of real income. When it is not, those locations are (relatively) spared. In either case, the policy maintains a considerable steady-state lockdown to avoid a re-emergence of the disease.\footnote{Figure A.2 shows that for a large shock affecting 1% of the population, or for a large value of life $\omega$ equal to 100 times the benchmark, the qualitative patterns in Seoul resemble those in Daegu and NYM.}

The optimal lockdown paths are further visualized in Figure 3. For each city, the figure shows the lockdown every 30 days. The initial lockdown pattern radiates from geographically central locations and weakens over time.

Online Appendix C shows that these patterns are robust to the alternative parametrizations described in the previous section.
4.2 Pareto Frontier: Uniform versus Spatially Optimal Lockdown

We compute a “Pareto” frontier describing the tradeoff between cases and economic costs. We solve the optimal lockdown for values of life $\omega$ ranging between $1/100$ and $100$ times the benchmark. To demonstrate the importance of spatially targeted policies, we also implement optimal uniform lockdown paths that are restricted to be constant over space. Figure 4 plots cumulative Covid-19 cases against cumulative economic cost at the last period of our data (April 30) across these values of $\omega$, in both the spatial optimum and the uniform cases. We also show the economic costs and cases in the estimated model at the observed reductions in commuting flows.

We find large gains from implementing optimal spatial lockdown. Compared to uniform optimization, and given the actual number of cases, spatially targeted lockdown leads to 15%, 28%, and 50% lower economic costs in Daegu, Seoul, and NYM, respectively. In NYM and Daegu, the gap in economic cost between uniform and optimal policies grows for higher values of life, when the number of cumulative cases is low.

The economic costs and actual cumulative cases were far from the optimal. Under spatial targeting, the same number of cumulative cases could have been reached at 13%, 18%, and 33% lower economic costs in Daegu, Seoul, and NYM, respectively.

4.3 Optimal and Observed Commuting Reductions

We now compare observed reductions in commuting with the model’s prediction of optimal flows. The left panel of Figure 5 shows the aggregate commuting flows relative to pre-pandemic values in the data and under optimal lockdown. Since the optimal policies are implemented at the time of lockdown, they are shown as a flat line until that time. The right panel shows inflows, with a breakdown between high and low centrality locations. In Daegu and NYM, the actual city-level reductions in commuting were close to the optimal benchmark. In New York, a 40% drop took place during the time leading up to the lockdown. In the model, the optimal lockdown in that period is very similar. We find a similar pattern in Daegu, where the average lockdown is relaxed over time, as in the data. However, the most central (peripheral) locations of both NYM and Daegu exhibited a weaker (stronger) reduction in commuting than the optimal. In Seoul, the actual reductions were stronger than in the data in all locations. These differences explain why the estimated economic costs from actual commuting responses were much larger than the spatially optimal ones, as observed in Figure 4.

5 Conclusion

Depending on data availability, our framework could be applied to other spatial scales, such as across cities, states, or countries. The model could also be used to study the optimal spatial deployment of a vaccine in limited supply, or to account for disease transmissions through shopping and leisure consumption. Finally, we have assumed that worker-job matches are kept constant in
the time frame we study, but the model could be modified to allow for potentially sluggish job reallocations as lockdowns unwind.
References

Figure 1: Commute Response and Disease Spread

Note: Figure reports the average daily changes in commute flows relative to the pre-pandemic levels, corresponding to the time fixed effects from the equation in Footnote 14. The time fixed effects are normalized to 1 on January 22, 2020. Weekdays (weekends/holidays) are denoted in darker (lighter) blue circles. The sample size is 968 for Daegu, 75,625 for Seoul, and 46,325 for NYM. Each observation is a district by date pair for Daegu and a district/county-pair by date tuple for Seoul and NYM from January 1, 2020 to April 30. The first vertical line denotes the date of the first case in Korea (top/middle) and the U.S. (bottom). The middle and the last vertical lines denote the date of the first case and the lockdown announcement in each city, respectively. Wild bootstrap standard errors are clustered by district for Daegu, and twoway-clustered by origin and destination for Seoul and NYM. Error bars show 95% confidence intervals. The right axis reports the daily new Covid-19 cases in Daegu (top), Seoul (middle) and NYM (bottom).
Figure 2: Centrality of Commuting Locations and Optimal Policies

(a) Daegu

(b) Seoul

(c) NYC Metro

Note: The left panel denotes the (log) centrality of a location (see footnote 24), normalized so that the most central location is 1. The right panel plots the optimal policies over time for each location in the network. The color of the line represents the centrality of the location in the network. The three most central locations in the network are indicated in the legend.

Note: The figure plots the optimal policy in the commuting area at different points in time. Redder colors denote more stringent lockdowns.
Note: The figures plot the cumulative number of new cases (y-axis, log scale) and the average real income lost per day between the date of the first confirmed case (see Appendix Table A.1) and April 30, 2020 for parametrizations of the value of life ($\omega$) ranging from 1/100 to 100 times the benchmark, in both the optimal lockdown with space and time variation (“Spatial”) and in the spatially uniform optimal solution with time variation only (“Uniform”, i.e., the same lockdown across all locations). The green triangle shows the case count and real income lost implied by the estimated model on April 30, 2020.
Figure 5: Changes in Commuting Flows: Optimal and Observed

(a) Daegu

(b) Seoul

(c) NYC Metro

Note: In the left panel, the dashed black line shows the aggregate commuting flows in each city starting from the date of the first confirmed case in each city. The solid and circled blue lines show the aggregate commuting flows implied by the optimal spatial policy. In the right panel, optimal and observed commuting responses are divided by top-3 centrality locations (darker shade) and the other locations.
Online Appendix

A  Numerical Implementation

This section describes how the optimal planning problem is numerically implemented.

A.1 Optimal control problem

Assuming that the matching function is $M_j \left( \tilde{I}, \tilde{S} \right) = \beta_j \tilde{I} \tilde{S}$, the optimal control problem (10) simplifies to

$$W = \max_{\chi(t)} \int_0^\infty e^{-(r+\nu)t} \sum_j \left[ U(j, t) + \frac{\nu}{r} \bar{U}(j, t) - \omega \gamma D I(j, t) \right] dt$$

subject to

$$\tilde{S}(t) = -S(t) \cdot \left[ H_S(t)^\prime \text{diag} (\beta) H_I(t) I(t) \right]$$  \hspace{1cm} (A.1)

$$\tilde{E}(t) = -\tilde{S}(t) - \gamma_I E(t)$$  \hspace{1cm} (A.2)

$$\tilde{I}(t) = \gamma_I E(t) - (\gamma_R + \gamma_D) I(t)$$  \hspace{1cm} (A.3)

$$\tilde{R}(t) = \gamma_R I(t)$$  \hspace{1cm} (A.4)

and

$$U(j, t) = U(j; t; S(t), \tilde{S}(t), E(t), \tilde{E}(t), I(t), \tilde{I}(t), \chi(t))$$

$$\bar{U}(j, t) = U(j; 0, 0, 0; S(t) + E(t) + I(t) + R(t)).$$

The present-value hamiltonian can be written

$$H(t) = \sum_j \left[ U(j, t) + \frac{\nu}{r} \bar{U}(j, t) - \omega \gamma D I(j, t) \right.$$ \hspace{1cm} (A.8)

$$\left. + \mu_S(j, t) \tilde{S}(j, t) + \mu_E(j, t) \tilde{E}(j, t) + \mu_I(j, t) \tilde{I}(j, t) + \mu_R(j, t) \gamma_S I(j, t) \right],$$

where $\mu_u = S, E, I, R$, are $J \times 1$ vectors of costate variables associated to each sickness status.

The first-order conditions of the problem are

$$\begin{bmatrix} S(t) \end{bmatrix} \left( \frac{D_S U(t) + \nu}{r} \frac{D_R U(t)}{r} \right)^\prime 1_{J \times 1} + \text{diag} (H_S(t)^\prime \text{diag} (\beta) H_I(t) I(t)) (\mu_E(t) - \mu_S(t))$$  \hspace{1cm} (A.5)

$$\begin{bmatrix} E(t) \end{bmatrix} \left( \frac{D_E U(t) + \nu}{r} \frac{D_R U(t)}{r} \right)^\prime 1_{J \times 1} + \gamma_I (\mu_I(t) - \mu_E(t)) = -\mu_E(t) + (r + \nu) \mu_E(t)$$  \hspace{1cm} (A.6)

$$\begin{bmatrix} I(t) \end{bmatrix} \left( \frac{D_I U(t) + \nu}{r} \frac{D_R U(t)}{r} \right)^\prime 1_{J \times 1} - \omega D \gamma D 1_{J \times 1}$$ \hspace{1cm} (A.7)

$$+ H_I(t)^\prime \text{diag} (\beta) H_S(t) \text{diag} (S(t)) (\mu_E(t) - \mu_S(t))$$

$$- (\gamma_R + \gamma_D) \mu_I(t) + \gamma_R \mu_R(t) = -\mu_I(t) + (r + \nu) \mu_I(t)$$

$$\begin{bmatrix} R(t) \end{bmatrix} \left( \frac{D_R U(t) + \nu}{r} \frac{D_R U(t)}{r} \right)^\prime 1_{J \times 1} = -\mu_R(t) + (r + \nu) \mu_R(t)$$  \hspace{1cm} (A.8)

$$\begin{bmatrix} \chi(t) \end{bmatrix} D_\chi H(t) = 0$$  \hspace{1cm} (A.9)
Further using (5) and (8) we obtain a system for wages at time \( t \) of the form
\[
H_j (w_1, \ldots, w_J) = \left( \sum_{u=S,E,I,R} \sum_{z=j} \sum_{k} N_u (k', j, t) \frac{w(j,k)}{\bar{z}(j)} \right)^{1-\sigma} \sum_{u=S,E,I,R} \sum_{z=j} \sum_{k} N_u (k, j, t) w_k \right)^{\frac{1}{\sigma}}.
\] (A.12)

where \( N_u (i, j, t) \) is given by (6).

### A.3 Solving the General Equilibrium Trade Model

We use two methods to compute the solution of the general equilibrium trade model at different stages of the numerical optimization:

#### Exact Solution

When solving the SEIR model forward, we compute the exact general equilibrium solution of the trade model by iterating over \( w(j,t) \) for each \( t \) on the goods market equilibrium equation given a distribution of the state variables. Specifically, combining (4) and (7) we obtain:

\[
w(j,t) = \frac{\sum_{k} Y(k,t) \left( \frac{\tau(j,k)}{\gamma_z(j,t)} \right)^{1-\sigma}}{\sum_{u=S,E,I,R} \sum_{k} \sum_{z} N_u (k, j, t)}.
\] (A.10)

Further using (5) and (8) we obtain a system for wages at time \( t \) of the form

\[
w(j,t) = H_j (w(1,t), \ldots, w(J,t), t)
\] (A.11)

where the operator \( H_j (w_1, \ldots, w_J) \) takes the form

\[
H_j (w_1, \ldots, w_J) = \left( \sum_{u=S,E,I,R} \sum_{z=j} \sum_{k} N_u (k', j, t) \frac{\tau(j,k)}{\bar{z}(j)} \right)^{1-\sigma} \sum_{u=S,E,I,R} \sum_{z=j} \sum_{k} N_u (k, j, t) w_k \right)^{\frac{1}{\sigma}}.
\] (A.12)

#### Gradients

When evaluating the Jacobians \( D_u U(t) \) and \( D_u \bar{U}(t) \) for \( u = S, E, I, R \) or when maximizing the Hamiltonian, we linearize the trade model around a nonlinear solution (the equilibrium under the current \( \chi \) to evaluate the Jacobian
and the current equilibrium with $\chi = 1$ for the Hamiltonian maximization).

Solving for the linearized equilibrium solely requires inverting a matrix for which we have an analytical expression. Specifically, totally differentiating the equilibrium conditions given shocks to the bilateral flows $d \ln N_u (j,i)$ of type-$u$ workers, and dropping the time subscript to save notation, we obtain the following linear system

$$d \ln Y = \sum_u (sR(u) \cdot d \ln N_u) 1_{J1} + \sum_u sR(u) d \ln w$$

$$d \ln w = s_X d \ln Y - (s_X \cdot d \ln s_M) 1_{J1} - \sum_u (sW(u) \cdot d \ln N_u)' 1_{J1}$$

$$d \ln P = s'M d \ln w$$

$$d \ln s = (1 - \sigma)(d \ln w) 1_{J1} - 1_{J1} (d \ln P)'$$

where the first line is the total differential of (5), the second line corresponds to (7), the third line differentiates the price index (8) and the last line is the changes in the expenditure share, and where we are using vector notation such that $[d \ln N_u]_{i,j} = N_u (i,j)$, $[d \ln Y]_j = d \ln Y (j)$, $[d \ln P]_j = d \ln P (j)$, $[d \ln w]_j = d \ln w (j)$, and $[s]_{ij} = s (i,j)$. In these expressions, we have also defined $s_X (i,j)$, $s_W (u,i,j)$, and $s_R (u,i,j)$ such that $s_X (i,j) \equiv \frac{\sum_{k=1}^{K} \lambda_k N_k (i,j)}{\sum_{k=1}^{K} \lambda_k N_k}$ is the fraction of resident of $j$'s efficiency units corresponding to commuter to $i$ in type $u$. We can summarize the expressions as a solution for wages as a function of expenditure shares and labor flows shares:

$$d \ln w = \Omega_w^{-1} \left( \sum_u s_X (sR(u) \cdot d \ln N_u) 1_{J1} - \sum_u (sW(u) \cdot d \ln N_u)' 1_{J1} \right)$$

(A.13)

where

$$\Omega_w = I_J - \sum_u s_X s_R (u) - (1 - \sigma) \text{diag} (s_X 1_{J1}) + (1 - \sigma) s_X s'.$$  

(A.14)

The gradients with respect to $\chi$, $S$, $E$, $I$ and $R$ then follow using the definition of $N_u (i,j)$ in (6).

### B Commuting and Infections Relationship

We follow Fang et al. (2020) to assess the relationship between new daily infections and 21-day lags of commuting in a reduced form specification:

$$\ln(1 + \text{new cases}_{it}) = \alpha_i + \gamma_{city(i),t} + \sum_{k=0}^{21} \beta_k \ln(flow_{i,t-k}) + \epsilon_{it}$$

(A.15)

where $\alpha_i$ is a district fixed effect and $\gamma_{city(i),t}$ is a fixed effect that varies by city and date $t$. This specification flexibly controls for city-level trends due to forces other than commuting. It identifies the impact of flows from cross-sectional variation by exploiting a district’s flows above or below its average. The variable $flow_{it}$ is either the total number of people who leave from district $i$ (outflows) or arrive into district $i$ (inflows). The specification pools over the three cities since number of districts in each city is small, but we weight the regression so that each city contributes equally. Standard errors are clustered by $i$ using the block bootstrap to account for a small number of clusters (Cameron et al., 2008).

We do not have an instrument for commuting that varies across space, so the coefficients must be interpreted with caution. For example, changes in commuting may be correlated with behavioral changes. Figure A.3 reports the coefficients. It shows an inverted-U shape peaking between 8-15 days when looking at inflows. The p-value of the joint test $\beta_k = 0$ for $k = \{0, \ldots, 7\}$ is 0.479, for $k = \{8, \ldots, 15\}$ is 0.045, and for $k = \{16, \ldots, 21\}$ is 0.452. The results for outflows are noisier and we do not target these moments in the structural estimation, but they seem consistent with an incubation period after which people showing symptoms get tested or come to the hospital.
C Robustness of Optimal Lockdown Patterns

We implemented robustness with respect to key parameters, as described in Section 3.3. We consider a lower infection fatality ratio (0.03%); a faster recovery time (10 days); an estimation of the transmission rate starting at the peak of new cases; an asymptomatic rate of half the benchmark; a large shock such that 1% of the population is infected; twice the value of life of the benchmark; and a shorter incubation (4.1 days). Figure A.4 shows that the qualitative patterns of optimal lockdown from the benchmark are similar across these specifications, except for Seoul given a large shock, as previously mentioned. Doubling the value of life or introducing a large shock leads to stronger initial lockdown, in particular for central locations, while a lower death rate weakens it.

Note: The table reports the parameters in the benchmark calibration and robustness exercises. The rate $\gamma_D$ is chosen such that the infection fatality ratio $0.009 = \gamma_D/\gamma_D + \gamma_R$, and the robustness uses 0.003 instead. See Section 3.3 for more details.
Figure A.1: New Cases per District: Data and Estimation

(a) Daegu  (b) Seoul  (c) NYC Metro

Note: The solid lines show the average number of new cases per district over time since the peak in new cases in the data. The dashed lines are the number of new cases by district in the estimated model corresponding to equation (17), assuming that commuting changed as observed in the data (the shade of the lines represent the share of commuter inflows, darker representing more inflows). The calibration is implemented using case data starting 10 days after the peak in new cases in each city. The solid line with circle markers is the total case number per district in the estimated model.

Figure A.2: Seoul: Optimal Lockdown in Baseline and Alternative Scenarios

(a) Baseline  (b) Large Shock  (c) High Value of Life

Note: The three panels show the results for Seoul under the baseline calibration (left panel), a large shock infecting 1% of the population (middle panel) and a value of life that is 100 times the benchmark (right panel).
Figure A.3: Commuting and New Daily Cases

Note: The figure plots the coefficients from (A.15). The left panel reports results using inflows as the independent variable. The right panel reports outflows as the independent variable. The regression pools over the three cities and applies weights so that each city contributes equally. The regression is run using data since January 22, 2020. Error bars show 90 percent (thick) and 95 percent (thin) confidence intervals. Standard errors are clustered by using the block bootstrap to account for a small number of clusters.
Figure A.4: Robustness

(a) Daegu

(b) Seoul

(c) NYC Metro

Note: Plotted optimal policies are defined as mean policy for high centrality vs other locations for each city. The different cases correspond to the alternative parametrizations described in Section 3.3 and discussed in Section C.
